THE POINCARÉ HOMOLOGY SPHERE

ISHAN LEVY

1. Introduction

In dimension < 3, any manifold with the homology of a sphere is in fact a sphere. However, this is not at all true in dimension 3. An easy way to see this is the following: given a Kirby diagram, the **linking matrix** is the matrix M_{ij} where the off diagonal terms are the linking numbers of the ith and j^{th} (oriented) knot in the diagram, and the diagonal terms are the framings on the components. Then this matrix represents the intersection form on the second homology of the 4-manifold. To see this, every time a 2-handle is added, by the Mayer-Vietoris sequence, we add a $\mathbb{Z}$ to homology. However the Mayer-Vietoris sequence gives an explicit generator of the new copy of $\mathbb{Z}$. Namely take a surface in D^4 that has boundary the knot, and glue it to the core of the 2-handle to get a surface in the 4-manifold. The self intersection of this can be computed by slightly translating the surface, in D^4, and computing the intersection with the original surface. To see the intersection number is the linking number, one makes each surface Morse with respect to the distance from the center of D^4, and then keeping track of how the linking number changes with the critical points.

If the 4-manifold is simply connected (which always happens if you attach 2-handles), then the by Poincaré duality and the universal coefficients theorem, $H_3(M, \partial M) = 0$, so we have the exact sequence:

$$0 \to H_2(\partial M) \to H_2(M) \to H_2(M, \partial M) \to H_1(\partial M) \to 0$$

If the intersection form is nondegenerate, then the image of $H_2(\partial M)$ is 0, as anything in the image is clearly null in the intersection form. Thus the exact sequence above gives that $H_2(\partial M) = H_1(\partial M) = 0$. Conversely if they are 0, the map in the middle is an isomorphism, so by Poincaré duality the intersection form is nondegenerate. Thus we get:

Theorem 1.1. *The linking matrix of a Kirby diagram has determinant ± 1 iff the associated 3-manifold is an integral homology sphere.*

Date: June 2, 2020.

This makes it very easy to produce lots of homology 3-spheres. Here we will study a very special one, called the Poincaré homology sphere, which will be denoted $\Sigma(2,3,5)$.

2. DESCRIPTIONS

The first description is as a plumbed 3-manifold, namely that of the E_8 graph shown below:

FIGURE 1. The $E8$ graph, where the associated plumbed 4-manifold has boundary the Poincaré

The second and third descriptions are as a Seifert fibre space and as -1 surgery on the left-handed trefoil knot, both of which are shown below:

FIGURE 2. Surgery descriptions of $\Sigma(2,3,5)$.

For the Seifert fibre space, it is an S^1-bundle over S^2 which is locally trivial except at 3 exceptional fibres, where the stabilizer of the S^1 action is $5, 3$, and 2 respectively.

The fourth description is the following: take $SO(3)$, and quotient by the isometries of the icosahedron, shown in Figure 3.

This description is especially concrete since $SO(3)$ is the unit sphere bundle on the icosahedron.

The fifth description is the following: consider the singular surface in $\mathbb{A}^3$ given by the equation $x^2 + y^3 + z^5 = 0$. If you take a small ball around the origin and intersect it with this hypersurface, the intersection will be the Poincaré homology sphere.

The sixth description is 3 in 1: for any $\{i, j, k\} = \{2, 3, 5\}$, $\Sigma(2, 3, 5)$ is the i-fold branched cover of the j, k torus knot (i.e. the knot representing (j, k) in the fundamental group of the standard torus in S^3.

3. EQUIVALENCES

The first step is to show that the first three are the same using Kirby calculus. Namely, whenever we have a ± 1 framed unknot, we can **blow down**. This means that we first slide all adjacent handles over this handle to leave the v disjoint from everything else, and then use the first Kirby move to remove the unknotted 2-handle. The reverse process is called blowing up. The effect of this on a graph is shown in Figure 4. Now that we can blow up and down, we can show the first and last Kirby

FIGURE 4. The effect of blowing up on a plumbing graph.

diagrams of the Poincaré homology sphere are the same by blowing up and down in Figure 5.

Finally, we can continue to blow down, obtaining the third description.

Now lets give some indication of how to get from the first to the 4th and 5th description. We can consider quotienting $\mathbb{C}^2$ by the **binary icosahedral group**, which is the pullback of the symmetry group of the icosahedron ($A5$) via the covering map $SU(2) \to SO(3)$. If we take the quotient of the unit sphere, we will get exactly the 3rd description. However, we can first take the quotient, and then take the boundary of a small ball to get the equivalence with the 4th description. To see this, we can take the quotient algebraically, which makes sense since the group is finite.
FIGURE 5. We can change our Kirby diagram for the Poincaré homology sphere by blowing up and down. In the above pictures, an unlabeled vertex has weight -2. By blowing up a 1 vertex on either side of the graph, we can then blow down many times, ultimately getting the second form of the Poincaré homology sphere.

FIGURE 6. By blowing down 3 more times, we get -1 surgery on a left-handed trefoil.

We view the group acting on $\mathbb{C}[x, y]$, and find the polynomials fixed by its action. There are three polynomials f_1, f_2, f_3 that will generate the fixed subalgebra, and these will satisfy exactly the relation $f_1^2 + f_2^3 + f_3^5 = 0$.

There are at least 2 ways to connect the fourth and fifth descriptions to the first three. In the fourth description, There is a natural S^1 action on $SO(3)$, given by clockwise rotation. On the Poincaré homology sphere, This action is almost free, except there are 3 points with nontrivial stabilizer. The centers of a vertex, edge, or face have nontrivial stabilizers of sizes $5, 2, 3$ respectively. There is a unique Seifert fibred homology sphere over a sphere with this property (this can be proved using Kirby calculus), so this shows that this description is the same as the second. One

can also see the Seifert fibration directly in the equation $x^2 + y^3 + z^5 = 0$. Namely, $S^1 = \mathbb{R}/30\mathbb{Z}$ can act on the points via $t(x, y, z) = (e^{\frac{2\pi it}{2}}x, e^{\frac{2\pi it}{3}}y, e^{\frac{2\pi it}{5}}z)$. The points where $z = 0$ or $x = 0$ or $y = 0$ are clearly the exceptional fibres.

There is an algebro-geometric way to get from the fifth description to the first. Namely, consider the singular 4-manifold that is a neighborhood of the origin in the 5th description. Then we can resolve the singularity by blowing up many times. In our particular case, when we blowup to resolve the singularity in a minimal way, there are 8 exceptional fibres, which transversely intersect as in the E_8 graph, and have self intersection -2. Then the preimage of the 4-manifold under this blowup is a regular neighborhood of these exceptional fibres, which is by an example in a previous lecture the plumbing on the E_8 graph. The boundary hasn't changed so it is still $\Sigma(2, 3, 5)$.

Finally, we can show that the 4th description is the same as the 6th. Namely, consider the map from $\Sigma(2, 3, 5) = \{(x, y, z) \in \mathbb{C}^3, x^2 + y^3 + z^5 = 0, |x|^2 + |y|^2 + |z|^2 = 1\}$ to $S^3 = \{(x, y) \in \mathbb{C}^2, |x|^2 + |y|^2 = 1\}$ given by $(x, y, z) \mapsto \frac{(x,y)}{|(x,y)|}$. This is the branched covering. To see this, since a nonzero complex number has 5 5th roots, there are 5 fibres except at the trefoil, which is defined as the points for which $x^2 + y^3 = 0$. Moreover the derivative is surjective where it needs to be so it is a branched cover, and there is a clear $\mathbb{Z}/5\mathbb{Z}$ action on the fibres given by multiplication on z by a 5th root of unity. Thus it is a normal branched cover with Galois group $\mathbb{Z}/5\mathbb{Z}$, but there is only one of these, namely the 5-fold cyclic branched cover. By permuting the $2, 3, 5$, we can get the other branched cover descriptions.
